Guidelines for the Genotyping of Mice and Rats

Purpose

Genotype is most often determined by the analysis of DNA extracted from tissues of young rodents. Analysis by Polymerase Chain Reaction (PCR) requires small amounts of DNA obtained from tail biopsies, ear punches, hair, blood, fecal or oral samples. Larger amounts of DNA are required for Southern Blot determination of the genotype.

Obtaining tissue from a mouse or rat for DNA analysis via tail biopsy is a safe, effective and humane procedure. Pain perception of tail clamping in rats does not start to develop until 12 to 14 days of age, so performing tail biopsy earlier in rodents may cause less pain. When performed properly in adult mice, it causes only minimal or transient pain and distress, and induces no more “physiological impact” (change in heart rate, body temperature, or activity level) than restraint of the animal for the procedure. DNA prepared from tail biopsies is suitable for analysis by either Southern Blot or PCR. Depending on the requirements of the study, investigators are urged to consider less invasive alternatives such as ear punches and noninvasive alternatives such as hair, fecal or oral samples.

Guidelines for Tail Biopsy

1. Procedures for tail biopsy for DNA analysis and/or genotyping must be included in an approved Animal Study Proposal (ASP) and described in the ASP or an IACUC approved SOP. When animals are 10 to 28 days of age, the pain category should be listed as C. When animals are older than 21 days, list animals in Category D.

2. Ideally, mice and rats should be 10-28 days old. At this age, the yield of DNA is highest. In addition, prompt analysis of tail tissue allows the desired mice and rats to be identified prior to weaning which can facilitate more efficient use of cage space.

   a. For mice and rats 10-28 days of age: Based on the physiological impact and rodent pain ontogeny studies, investigators are to apply local anesthesia to the tail and to conduct tail biopsy as early as possible within this age range. Local anesthesia may be achieved by immersion of the tail in ice cold ethanol for 10 seconds, by an application of ethyl chloride spray or suitable preparation such as EMLA cream.

   b. For mice and rats greater than 28 days of age: The use of a local or general anesthetic is required prior to collection of tissue. Refer to Anesthesia Guidelines if a general anesthetic is to be used.

   c. For rats greater than 35 days of age: The use of a general anesthetic is required.

3. Manually restrain the mouse or rat between thumb and forefinger. This is a convenient time to identify the animals using the appropriate method (i.e. ear punch, ear tag, transponder etc.).

4. With a sterile scalpel, razor blade, or scissors cleanly excise the distal 2mm (maximum 5 mm) of the tail. If the proper procedures are followed, the yield of DNA from 5 mm of tail should be enough for multiple analyses. The yield of DNA does not proportionally increase as tail
fragments larger than 5mm are used. If small amounts of DNA are required, investigators should consider taking only 2 mm of tail. If the analysis of the DNA is to be performed by PCR, great care should be taken to remove all tissue from the scissors or scalpel after each animal. Disinfect the scalpel or scissors between animals. If a scalpel is used, also disinfect the work surface on which the tail is placed between animals.

5. The investigator must monitor the animals to assure hemostasis after the animals are returned to the cage. If needed, apply digital pressure, silver nitrate, Kwik Stop powder, or heated instrument.

6. If additional DNA is needed for retesting, alternatives to a second tail biopsy should be considered. Repeat tail biopsies require anesthesia and must be justified in the ASP. The use of post-procedural analgesia should be considered.
